EXECUTIVE REPORT

Microeconometric Modelling for Business Analytics (R)

Group 4: Leila Abduraufova, Irene Peña, Katharina Rodríguez, Xinyi Zhu

INDEX

1. Business Understanding

- **1.1 Problem Definition:** Identification of the real business issue.
- **1.2 Stakeholder Identification:** Who is affected and who the decision-makers are.
- **1.3 Research Question and Objectives:** Explanatory and inferential goals.
- **1.4 Economic Justification and Theoretical Hypotheses:** Expected relationships based on theory.
- **1.5 Managerial Implications:** How the findings will impact business strategy.

2. Data Understanding and Preparation

- **2.1 Dataset Overview:** Description of the selected dataset.
- **2.2 Variable Description:** Detail of dependent variables and independent predictors.
- **2.3 Data Preparation (Cleaning and Summary)**
- **2.4 Transformation and Exploration (EDA)**

3. Linear Model (OLS)

- **3.1 Model Specification:** Variables included in the linear regression.
- **3.2 Beta Interpretation:** Analysis of the coefficients and their statistical significance.
- **3.3 Feature Selection (Stepwise):** Refining the model to optimize the Adjusted R^2.
- **3.4 Diagnostics:** Checking for Multicollinearity (VIF) and Heteroscedasticity.
- **3.5 Regularization (Lasso):** Using Lasso regression for variable selection and to prevent overfitting.
- **3.6 Conclusion**

4. Poisson Model (GLM Poisson)

- **4.1 Count Data Modelling:** glm(family = poisson) for the count dependent variable.
- **4.2 IRR (Incidence Rate Ratios):** Exponential betas to interpret the impact on rates.
- **4.3 Goodness of Fit:** Analysing Deviance (Null vs. Residual).
- **4.4 Overdispersion Analysis:** Checking if the variance exceeds the mean.
- **4.5 Graph**
- **4.6 Conclusion**

5. Logit Model (GLM Logistic)

- **5.1 Binary Modelling:** glm(family = binomial) for the binary outcome.
- **5.2 Odds Ratios Interpretation:** Exponential betas to understand relative probabilities.
- **5.3 Model Performance:** Evaluation through Pseudo R^2 and Deviance analysis.
- **5.4 Conclusion**

6. Evaluation and Deployment (Executive Summary)

- **6.1 Main Determinants:** Assessing consistency with the economic hypotheses.
- **6.2 Business Implications:** potential biases, sample issues, and the associated impact.
- **6.3 Strategic Recommendations:** Key determinants and business insights.

7. Overall conclusion

8. Bibliography

1. Business Understanding

1.1 Problem Definition

Companies nowadays face significant challenges when it comes to distinguishing high-potential candidates from a large pool of applicants. Traditional hiring methods are often limited, which can lead to inefficiencies and missed opportunities.

The primary objective of this study is to transform student data into predictable hiring intelligence. By using advanced statistical modelling, we aim to provide the company with a data-driven roadmap to identify, attract, and value talent efficiently.

1.2 Stakeholder Identification

- ***HR & Recruitment Departments:*** The primary stakeholders within the company who will use the findings of this study. They are responsible for identifying which candidate attributes are the most reliable predictors of market value and future performance.
- ***Students:*** Understanding which factors influence employability and salary outcomes can help them make more informed decisions about their education and skill development.

1.3 Research Question and Objectives

This study is guided by a set of explanatory and inferential research questions aimed at understanding the key factors that drive candidate success in the labour market. Each model addresses a specific dimension of the hiring process

Linear Model

Objective: To set competitive and fair salary benchmarks.

Questions: Which factors most influence a candidate's starting salary?

Poisson Model

Objective: To identify candidates with the highest market demand, or to target those with lower demand in order to reduce costs and minimize volatility risk.

Questions: Which factors influence how many job offers a candidate receives? How can we identify high-demand candidates versus lower-risk candidates? What should we consider when hiring employees regarding their job offers?

Logit Model

Objective: To optimize gender diversity and specialized recruitment.

Questions: Can candidate characteristics explain their gender?

1.4 Economic Justification and Theoretical Hypothesis

The modern labour market operates under Information Asymmetry. Employers cannot know a candidate's true productivity just by looking at them. To minimize the "Cost of a Bad Hire," companies rely on Signaling Theory. Candidates use “signals” such as GPA, internships, and certifications to demonstrate their potential value.

This study justifies the cost of recruitment by identifying which signals are the most reliable predictors of performance and market demand. By understanding these relationships, a company can optimize its decisions and budgets

Theorical Hypothesis

H1: Higher university GPA and certifications are positively associated with starting salary.

H2: Superior soft skills and networking scores are positively associated with number of job offers

H3: Male candidates are expected to receive a significantly higher number of job offers

1.5 Managerial Implications

The primary goal of this research is to shift the company’s hiring process from an intuition-based approach to a more data-driven recruitment strategy. By applying statistical analysis to student and market data, the study aims to deliver several key benefits, including defining a clear “success profile” for candidates, improving accuracy in compensation budgeting, and supporting more effective diversity sourcing strategies (DEI).

2. Data Understanding

2.1 Dataset Overview

The dataset used in this analysis was sourced from Kaggle (Education & Career Success) and contains information on 400 college graduates from universities across multiple U.S. states.

The dataset includes 20 different variables that track student backgrounds, their grades, work experience, among other variables. It gives us the three types of data we need to run our models: a continuous variable (**Starting Salary)**, a count variable (**Job Offers)** and a binary variable (**Gender)**.

2.2 Variable Description

Variable	Description	Type
Student_ID	Unique identifier	Categorical
Age	Student age	Continuous
Gender	Male/Female	Categorical
High_School_GPA	GPA in high school	Continuous
SAT_Score	SAT score	Continuous
University_GPA	University GPA	Continuous

Field_of_Study	Major	Categorical
Internships_Completed	Number of internships	Discrete (count)
Projects_Completed	Number of projects	Discrete (count)
Certifications	Number of certifications	Discrete (count)
Soft_Skills_Score	Soft skills rating (1–10)	Ordinal
Networking_Score	Networking ability score (1–10)	Ordinal
Job_Offers	Number of job offers	Discrete (count)
Starting_Salary	First salary	Continuous (response variable)
Career_Satisfaction	Satisfaction score (1–10)	Ordinal
Years_to_Promotion	Years until promotion	Discrete
Current_Job_Level	Entry / Mid / Senior	Ordinal categorical
Work_Life_Balance	Score 1–10	Ordinal
Entrepreneurship	Yes/No	Binary categorical
Dichotomous_Gender	1 = Male, 0 = Female	Binary

2.3 Data Preparation

To make sure our results are accurate, we cleaned and organized the data before running any tests. We first checked for missing values (NAs) to prevent errors in our calculations and ensure the dataset was complete. Next, we filtered out observations that were inconsistent to maintain the quality and reliability of the sample.

Choosing the Target Variables

We picked a specific Y variable for each of our three models based on what the company needs to know.

Linear Model → Starting Salary (Continuous)

We chose this to measure market value. It tells the company exactly how much a specific set of skills is worth in dollars.

Poisson Model → Number of Job Offers (Discrete Count)

We chose this to measure market demand. It tells the company how "competitive" a student is.

Logistic Model → Gender (Binary)

We chose this to measure Hiring Trends. It helps the company see if their current requirements are filtering for one gender over another.

2.4 Transformation and Exploration

We applied several transformations and adjustments to the data to ensure that the results obtained from our models would be as accurate and reliable as possible. We transformed the "Gender" category into a dichotomous format (1 for Male, 0 for Female). This makes it easier to see if being in one group or the other changes the probability of getting more job offers or a higher salary.

3. Linear Model (OLS)

3.1 Model Specification

In Model 0, all possible variables are included, this way it is possible to see which ones are influencing the starting salary. After testing statistical significance, variables that do not meaningfully impact salary decisions are removed, Age, High School GPA, SAT Score…, these variables are examples of the ones that do not show reliable relationship with salary, they present high p-values, this means that they do not systematically affect how much candidates are paid.

The model 5 keeps only variables that consistently explain salary differences, University GPA , Internships Completed, Projects Completed, Certifications, Work-Life Balance, Gender, Job Offers, Years to promotion. This model is chosen as it has a high R^2, gets up to the value of 0,977, this translates into 97,7% of explanation of the salary variation, it has a very high explanatory power where all variables are statistically significant.

3.2 Beta Interpretation

```
Coefficients:
                    Estimate Std. Error t value Pr(>|t|)
(Intercept)          -9537.1    15035.4  -0.634 0.526247

F-statistic:  2072 on 8 and 391 DF,  p-value: < 2.2e-16
```

Each coefficient (beta) shows how salary changes when that factor increases by 1 unit, holding everything else constant.

- *University GPA (+22,004):* shows strong positive effect, higher GPA means higher salary. By each increased unit in GPA the salary will increase in 22,004$. Academic performance at the university level is seen as a credible signal of ability and discipline.
- *Internships Completed (−15,298*): more internships means lower salary, this might not be the expected result, however there are some possible explanations. Candidates with many internships may stay longer in a low-paid trainee roles, there is a signal of lack of specialization or direction. As well as high performers may need fewer internships before landing strong offers.
- *Projects Completed(+2,002):* by each increasement in unit of projects there is an increasement of 2002$ of salary. This reflects that, Practical, hands-on work is valued by employers, as there is a signal of execution ability and real-world problem solving experience. It is recommendable to prioritize candidates who build things, not just study.
- *Certifications (+14,132):* there is a very large positive effect, certifications are market recognized proof of skills, this is why by each additional certificate the salary is expect to be 14,132$ higher. This is especially important in Tech, data and business tools. Certifications reduce uncertainty.
- *Work-Life Balance (-1,645):* Higher preference of a greater working balance means lower salary, candidates prioritizing balance may choose lower-paying roles and avoid the higher pressure that the high-paying jobs might offer. There id a clear trade-off between compensation and lifestyle expectations.
- *Gender(+4,138):* Males earn more on average, this reflects the market bias, negotiation differences and industry composition. There is a potential inequality signal, not necessarily productivity based.
- *Job offers(+9,719):* More offers translates into much higher salaries, salary is strongly driven by market competition, candidates with multiple offers have bargaining powers due to that they are able to negotiate higher pay. Hiring top talent requires competitive offers, not just good roles.
- *Years to promotion(-2,778):* the longer the time of promotion id the lower the starting salary will be. Faster promotion track is associated with, higher initial compensation and stronger candidates, high-potential candidates are paid upfront and promoted faster.

Overall, the results show that starting salaries are primarily driven by demonstrated skills, certifications, and market demand, rather than background characteristics. Variables such as university performance, practical projects, and especially certifications significantly increase salary, confirming that employers value proven capability and job-readiness. At the same time, market dynamics play a crucial role: candidates with more job offers command higher salaries due to stronger bargaining power. Some counterintuitive findings, such as the negative impact of internships, suggest that quality and signalling matter more than quantity of experience. Additionally, trade-offs emerge between salary and personal preferences like work-life balance, and the gender effect highlights potential structural biases in the market. For entrepreneurs, the key

takeaway is to focus on skills-based hiring, remain competitive in offers, and critically assess traditional indicators of talent.

3.3 Feature Selection (Stepwise)

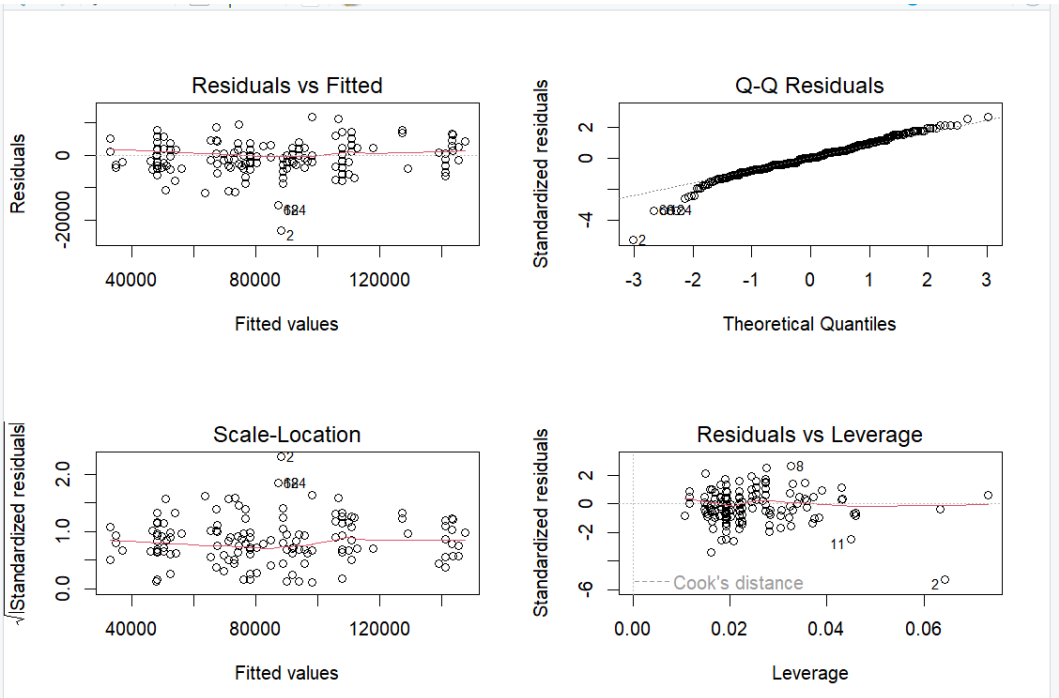

The application of backward, forward, and both-direction stepwise selection methods (based on AIC) leads to the same final model specification, confirming the robustness and consistency of the selected predictors.

From a statistical perspective, the final model maintains a very high explanatory power ($R^2 \approx 0.9775$), similar to the full model, while achieving a lower AIC (7877.98 vs 7885.09). This means that the stepwise approach improves the efficiency of the model, reducing unnecessary complexity without sacrificing predictive accuracy. In practical terms, the model becomes more interpretable and actionable for decision-making.

While the stepwise model improves parsimony and slightly reduces prediction error, it does not fully resolve underlying structural issues in the data. Therefore, the model is strong for prediction and strategic insight, but results should be interpreted with caution when making precise causal or policy decisions.

3.4 Diagnostics

To ensure the reliability of the findings in Model 5, we conducted a diagnostic assessment of the residuals. This process confirms that the model's estimates are unbiased and that the statistical inferences (p-values and confidence intervals) are valid.

The **Residuals vs Fitted** plot displays a random scatter of points around the horizontal zero line. The red trend line is relatively flat, indicating that the relationship between the predictors and starting salary is truly linear. There are no obvious "U-shaped" patterns, which suggests we have not missed any significant non-linear interactions.

The **Normal Q-Q** plot shows the residuals following the dashed diagonal line closely for the majority of the data.

- **Observation:** There is some "heavy-tailing" at the lower part of the plot, which might result in an inconsistency. However, while the errors aren't perfectly normal, the sample size is large enough (n=400) that the Central Limit Theorem applies, allowing us to trust the significance tests.

The **Scale-Location** plot help us see whether the model's prediction errors stay consistent across different salary levels. The mostly flat red line suggests that this is the case. In simple terms, the model performs with a similar level of accuracy for both lower and higher salaries, making its predictions reliable across the entire dataset.

The **Residuals vs Leverage** plot shows whether any individual data point is having too much influence on the regression results. In this case, all observations fall within the acceptable limits (Cook's Distance), meaning no point is excessively affecting the model. Although observation 2 has relatively high leverage and a larger error, it still remains within the safe range, so it does not distort the overall results. In simple terms, no single candidate is disproportionately influencing the model's conclusions.

Based on the **error metrics**, the linear regression model demonstrates excellent predictive accuracy. The MAPE of 4.40% indicates that the average percentage error is very low, placing the model within a highly reliable range for decision-making purposes. The MAE of approximately $3,387 shows that, on average, predictions deviate only slightly from actual salaries, which is reasonable given the salary scale analysed.

Additionally, the difference between the MAE and the RMSE ($4,501) suggests the presence of some larger errors in a small portion of the data. This aligns with the diagnostic analysis, where a few observations showed higher influence (e.g., via Cook's Distance). However, these cases are limited and do not significantly impact the overall performance of the model.

The **VIF results** show high multicollinearity, meaning several variables (such as University GPA, internships, certifications, and job offers) are strongly correlated because they all capture similar aspects of a candidate's skills and experience. We do not remove these variables because they are essential to explain salary differences, and dropping them would reduce the model's explanatory power without solving the issue. This multicollinearity affects the **Internships Completed** coefficient, which appears negative. This can be explained by the data: not all internships are high-quality or well-paid and some candidates accept lower salaries to gain experience.

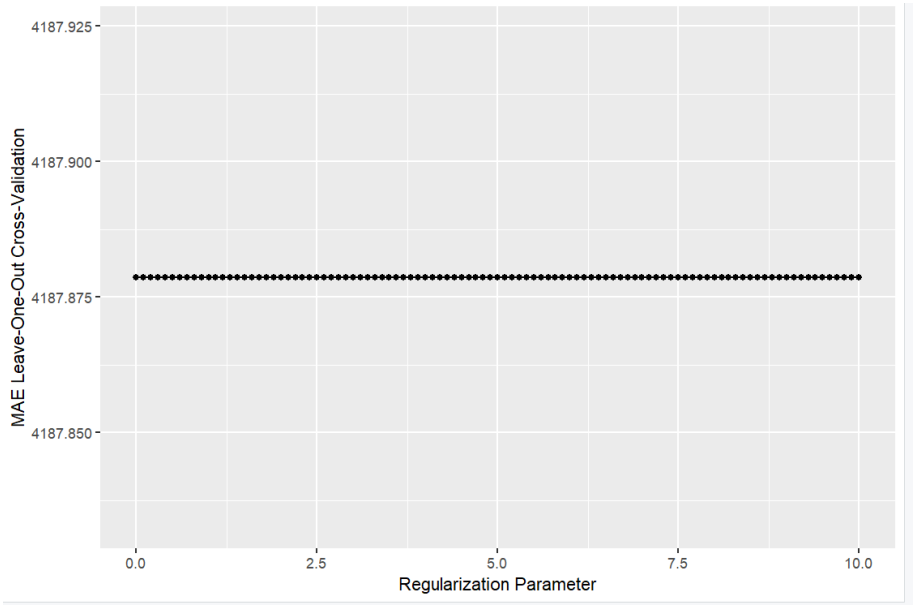

The **Jarque-Bera test** indicates a rejection of normality (p-value < 0.001), suggesting that the residuals are not perfectly normally distributed. However, given the large sample size (n > 30), the Central Limit Theorem supports the assumption that the model estimates remain approximately normally distributed, ensuring the validity of statistical inference.

Additionally, the QQ plot shows that the residuals follow a reasonably straight line, indicating that deviations from normality are not severe. Therefore, despite the test result, the normality assumption can be considered acceptable for practical and decision-making purposes.

The **Breusch-Pagan test** indicates the presence of heteroskedasticity (p-value < 0.001), meaning that the variance of the errors is not constant across observations. In practical terms, this implies that the model's prediction errors vary depending on the salary level.

This is a common pattern in salary data: it is relatively easy to predict salaries for entry-level positions, where variability is low, but much more difficult for higher-level profiles, where salaries can vary widely depending on factors such as negotiation, specialization, or company differences. While this does not invalidate the model, it suggests that predictions are more precise for lower salaries than for higher ones.

3.5 Regularization (Lasso)

The horizontal line in the visualization indicates that the model's predictive error does not fluctuate significantly as the penalty increases. This suggests that the predictors included (University GPA, Internships, Certifications, and Soft Skills) have such high explanatory power that the regularization penalty does not drastically alter their impact within the tested range.

LASSO suggests the reinforcement of the findings of the earlier Linear Model. Even under the pressure of regularization, all four variables remained in the model. This confirms that GPA, Certifications, and Internships are not just statistically significant, but are robust drivers of salary that do not "drop out" when the model is penalized.

The LASSO model places an even higher weight on University GPA and Certifications compared to the OLS model. For an executive, this underscores that while many factors matter, academic excellence and specialized certifications are the "heavy hitters" in determining market value.

The negative coefficient for Internships persisted in the LASSO model. This confirms that the negative relationship is a real feature of this dataset and not a fluke of OLS estimation, further supporting the theory that "quantity of internships" may signal a lack of early specialization or a longer tenure in trainee-level roles.

3.6 Conclusion:

Companies should adopt a skills-based hiring approach, prioritizing candidates with strong academic performance, relevant certifications, and practical project experience, as these are the main drivers of salary and value. Rather than focusing on the number of internships, firms should evaluate their quality and relevance. To attract top talent, it is essential to remain competitive in salary offers, especially for candidates with multiple opportunities. Additionally, companies should recognize trade-offs such as work-life balance preferences and ensure fair, performance-based compensation by being aware of potential market biases.

4. Poisson Model

4.1 Modelling

To identify the candidates that the business should hire, we have created this poisson model.

The dependant variable is the discrete variable number of jobs offers. The rest of the independent variables featured in the model because these are the ones we estimated that could have an impact in the popularity of the student, meaning that have an impact in job offers. After computing the code, we can see that the only significant variable is Intership_Completed, so we will only take this one into account.

```
modelo_poisson <- glm(Job_Offers ~ University_GPA +
                        Internships_Completed +
                        Projects_Completed +
                        Certifications +
                        Soft_Skills_Score +
                        Networking_Score,
                      family = poisson(link = "log"),
                      data = education)

summary(modelo_poisson)
```

Output:

```
Coefficients:
                    Estimate Std. Error z value Pr(>|z|)
(Intercept)        -1.30153    1.39968  -0.930   0.3524
University_GPA      0.27991    0.57826   0.484   0.6283
Internships_Completed  0.33188    0.13814   2.402   0.0163 *
Projects_Completed     0.10705    0.07819   1.369   0.1710
Certifications     -0.11046    0.09343  -1.182   0.2371
Soft_Skills_Score  -0.30861    0.58491  -0.528   0.5978
Networking_Score    0.35314    0.58137   0.607   0.5436
```

4.2 Incident Rate Ratios (IRR)

To understand the impact of the internships in the number of jobs offers, we use the Incident Rate Ratio, that converts to real world percentage.

```
irr <- exp(coef(modelo_poisson))
irr
```

Output:

```
> irr
        (Intercept)       University_GPA Internships_Completed    Projects_Completed
          0.2721140           1.3230154           1.3935810           1.1129898
     Certifications     Soft_Skills_Score      Networking_Score
          0.8954232           0.7344690           1.4235327
>
```

The result 1.3936 tells us that for each increase in 1 unit of internships, the number of jobs offers is multiplied by 1.3936 or in a 39.3%

4.3 Goodness of fit

The goodness of fit measures how well the model's predicted counts align with the actual counts observed in your data.

```
null_deviance <- modelo_poisson$null.deviance
resid_deviance <- modelo_poisson$deviance
reduccion_error <- (null_deviance - resid_deviance) / null_deviance
reduccion_error
```

Output:

```
> reduccion_error
[1] 0.9267081
```

In a perfect Poisson scenario (goodness=1), the mean and the variance are equal. The value of 0.92 then ensures that the findings are not being distorted by extreme outliers or messy data patterns. Ultimately, this is a robust and reliable model that proves internships have a powerful, measurable effect on job offers.

4.4 Dispersion

The dispersion can be imputed with the previous result being less than 1, but this code confirms we have a case of under dispersion in our model, because the output value id far less than 1.

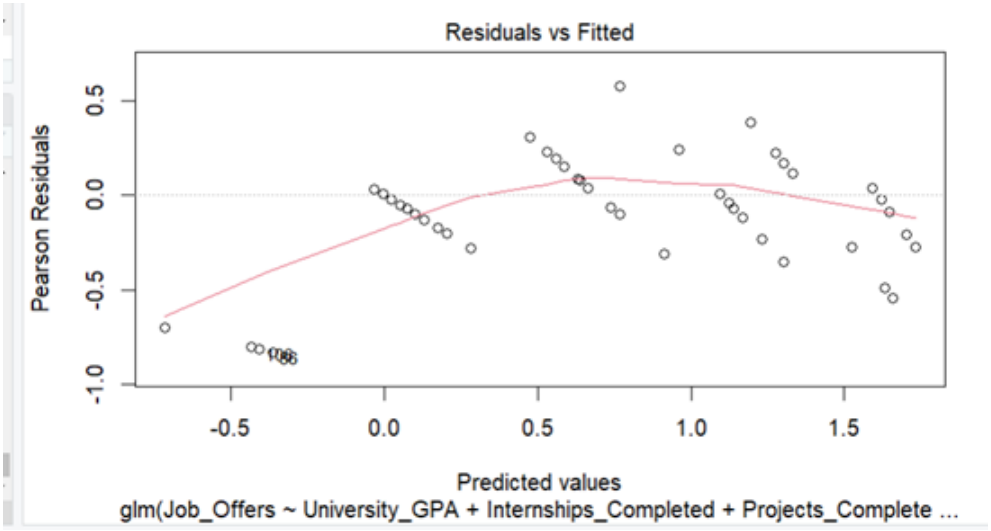

```
dispersion_poisson <- resid_deviance / modelo_poisson$df.residual
dispersion_poisson
```

Output:

```
> dispersion_poisson
[1] 0.05528148
```

The under dispersion means there is less variability than expected in our model. This happens because the data is really concentrated within the same results. Most people have the same amount of job offers, not outliers. This reflects the homogeneity and consistency of the dataset.

4.5 Graph

This graph "summarizes" the model by showing that while it's not a *100% perfect* geometric fit (due to that slight curve), it is unbiased and stable. It provides the visual evidence that the model is appropriate for this data and that the relationship for internships is fine.

4.6 Conclusion

The results are clear and how to act depends on the company:

One of the options is to hire candidates with the highest market demand and readiness, with more internships completed in order to attract great talent.

However, there is the options attract the ones with the lowest market demand, less internships completed, in case they want to lower the costs, or reduce the risk of volacity that could happen with the employees in the first option.

5. Logistic Model (GLM Logistic)

5.1 Binary Modelling

```
Coefficients:
                        Estimate Std. Error z value Pr(>|z|)
(Intercept)             15.5487     4.7234   3.292 0.000995 ***
University_GPA          -4.5446     1.9423  -2.340 0.019293 *
Internships_Completed    0.8730     0.5398   1.617 0.105805
Projects_Completed      -1.2808     0.2645  -4.843 1.28e-06 ***
Certifications           1.3737     0.4108   3.344 0.000825 ***
Soft_Skills_Score       -0.0738     1.6204  -0.046 0.963675
Networking_Score         0.4135     1.6140   0.256 0.797782
---
Signif. codes:  0 ‘***’ 0.001 ‘**’ 0.01 ‘*’ 0.05 ‘.’ 0.1 ‘ ’ 1
```

The objective of this model is to identify behavioural patterns and "human capital signals" that differ by gender. By using a Logit model, we treat gender as a binary choice influenced by academic and professional decisions.

Readjusted Model:

```
Coefficients:
                    Estimate Std. Error z value Pr(>|z|)
(Intercept)          12.5150     3.9651   3.156   0.0016 **
University_GPA       -3.0404     1.4625  -2.079   0.0376 *
Projects_Completed   -1.1089     0.2399  -4.623 3.78e-06 ***
Certifications        1.8486     0.3169   5.834 5.41e-09 ***
---
Signif. codes:  0 ‘***’ 0.001 ‘**’ 0.01 ‘*’ 0.05 ‘.’ 0.1 ‘ ’ 1
```

Significance Analysis:

According to the model summary, three variables are statistically significant (p-value < 0.05):

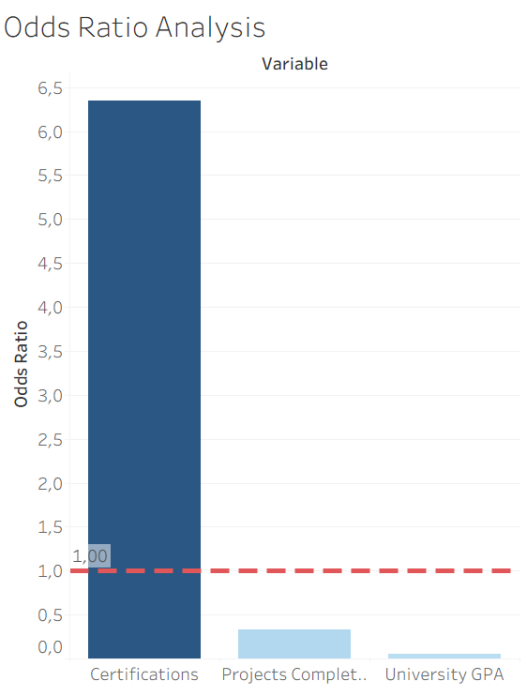

- **Certifications:** the most significant predictor (p < 0.001), indicating a clear distinction in how external credentials are distributed between genders.
- **Projects_Completed:** also highly significant predictor (p < 0.001), showing a strong negative correlation with the probability of being male.
- **University_GPA:** significant at the 5% level, suggesting that academic performance is a relevant differentiator in this dataset.

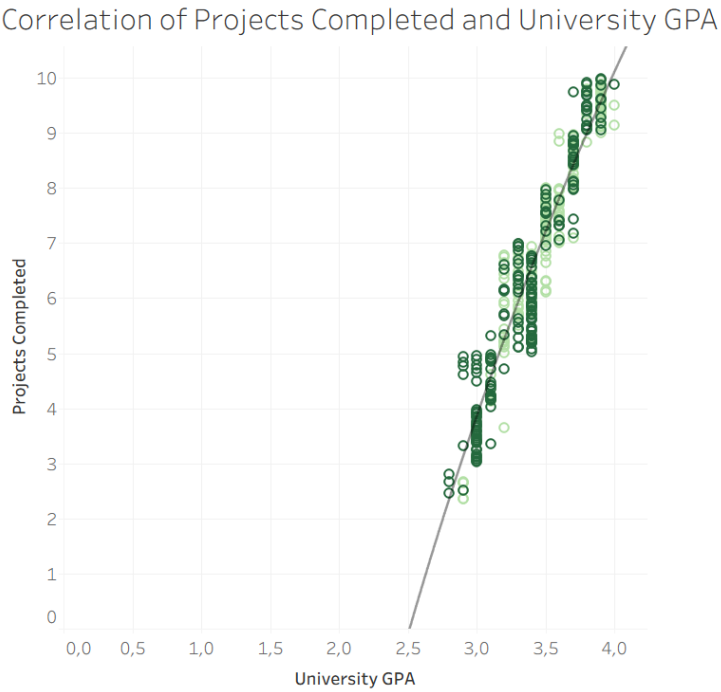

5.2 Odds Ratios Interpretation

```
  (Intercept)      University_GPA Projects_Completed      Certifications
2.723811e+05       4.781658e-02       3.299333e-01       6.351193e+00
```

To translate the mathematical coefficients into actionable business insights, we look at the Odds Ratios (OR):

- **Certifications (OR: 6.35):** For every additional certification earned, the odds of the student being male increase by 635**%**. From a business perspective, this suggests that the male demographic in this sample is significantly more likely to pursue professional certifications.
- **Projects_Completed (OR: 0.33):** For every additional project completed, the odds of being male decrease by 67**%** (calculated as 1 - 0.33). This indicates that a high volume of completed projects is a strong "signal" of a female profile in this labour market segment.
- **University_GPA (OR: 0.05):** A higher GPA significantly reduces the odds of being male. This suggests that, in this specific dataset, female students tend to maintain higher academic averages.

The scatter plot reveals a strong linear correlation between academic success and practical engagement. As shown above, the density of dark green markers (females) at the higher end of both scales visually justifies the logistic model's finding: high performance in these two areas serves as a primary signal for female candidates.

5.3 Model Performance

```
fitting null model for pseudo-r2
         llh       llhNull            G2      McFadden          r2ML          r2CU
-238.9622084 -277.2588722    76.5933275     0.1381260     0.1742666     0.2323555
```

- **Pseudo R^2 (McFadden)**

The McFadden value is 0.138. In logistic regression, values between 0.1 and 0.3 represent a healthy and reliable fit. It indicates that the model has real discriminative power without being “overfitted”. The model explains approximately 13.8% of the variability in the probability of gender based solely on merit-based signals. This is a consistent result that detects real market trends without being deterministic.

- **Logistic Dispersion Analysis**
  The calculated dispersion is 1.207, this value is very close to 1, which confirms that the model does not suffer from significant overdispersion. The statistical inferences regarding Certifications, Projects and GPA are valid and reliable. The model's error levels are controlled, making these results a solid foundation for strategic HR or diversity and inclusion policy-making.

5.4 Conclusion

In conclusion, the model shows that men and women use different signals: men stand out in Certifications, while women stand out in GPA and Projects. If a company only values one type of credential, it will create an unintentional gender bias. Therefore, recruitment should focus on actual job performance to capture the best talent regardless of how they demonstrate their attributes.

6. Evaluation and Deployment (Executive Summary)

6.1 Main Determinants of Candidate Success

The analysis identified several key factors that influence market value and demand:

- **Starting Salary Drivers:** University GPA and professional certifications are the strongest positive predictors of salary.
- **Market Demand:** The number of internships completed is the primary driver for job offers; each additional internship increases the expected number of offers by 39.3%.
- **Gender-Specific Signaling:** The models reveal that men often stand out through professional certifications, while women typically demonstrate higher university GPAs and a greater volume of completed projects.

6.2 Business Implications

- **Shift to Data-Driven Recruitment:** Moving from intuition-based hiring to statistical analysis allows for the definition of a clear "success profile".
- **Compensation Accuracy:** By understanding the dollar value of specific skills, companies can set competitive and fair salary benchmarks, optimizing their overall recruitment budgets.

- **Mitigating Unintentional Bias:** Recognizing that different genders utilize different signals to demonstrate talent is crucial for avoiding structural biases.

6.3 Strategic Recommendations

1. **Prioritize Quality Over Quantity:** Evaluate the relevance and quality of internships rather than just the total number, as a high volume of low-level internships can signal a lack of specialization.
2. **Optimize Talent Sourcing Strategy:**
    a. To **attract top talent**, target candidates with high market demand (multiple internships and offers) and be prepared to provide competitive salary packages.
    b. To **reduce costs and volatility**, consider targeting high-potential candidates with fewer internships who may have lower current market demand but possess strong foundational signals like a high GPA.
3. **Enhance Diversity and Inclusion:** Broaden the criteria for talent evaluation to include a mix of GPA, projects, and certifications to ensure the recruitment process captures the best talent across all demographics.

7. Conclusion

Wrapping up, what we might highlight from these three models is that we are giving the company the tools to hire the right candidates for their vacant jobs and give them the recommended salary so target companies can optimize their budgets. All of this taking into the account unintentional gender bias. We are also helping graduate students to have an idea of which skills they should acquire and the salary they will receive when they enter the labour market.
